```
graph TD; Genome --> Genes[Genes (DNA)]; Genes --> RNA[RNA mRNA]; RNA --> Proteins; Proteins --> Phenotype; Genes -- Replication --> Genes; RNA -- Translation --> Proteins; Proteins -- "Metabolism Physiology" --> Phenotype;
```

The diagram illustrates the Central Dogma of Molecular Biology, showing the flow of genetic information from the genome to the phenotype. The process begins with the **Genome**, which leads to **Genes (DNA)**. From **Genes (DNA)**, the process branches into **Replication** (indicated by a curved arrow) and **Transcription** (indicated by a downward arrow). **Transcription** leads to **RNA** (specifically **mRNA**). From **mRNA**, the process continues to **Translation** (indicated by a downward arrow), which produces **Proteins**. Finally, **Proteins** lead to the **Phenotype**, with **Metabolism** and **Physiology** (indicated by a downward arrow) being the processes that connect proteins to the phenotype.

A large collection of various chili peppers arranged in four rows, showing a wide variety of shapes, sizes, and colors including red, yellow, green, black, and orange. The peppers include bell peppers, jalapeños, serranos, and many other varieties, all displayed against a plain white background.

Phenomics allows to measure a number of traits in different genetic backgrounds and environments

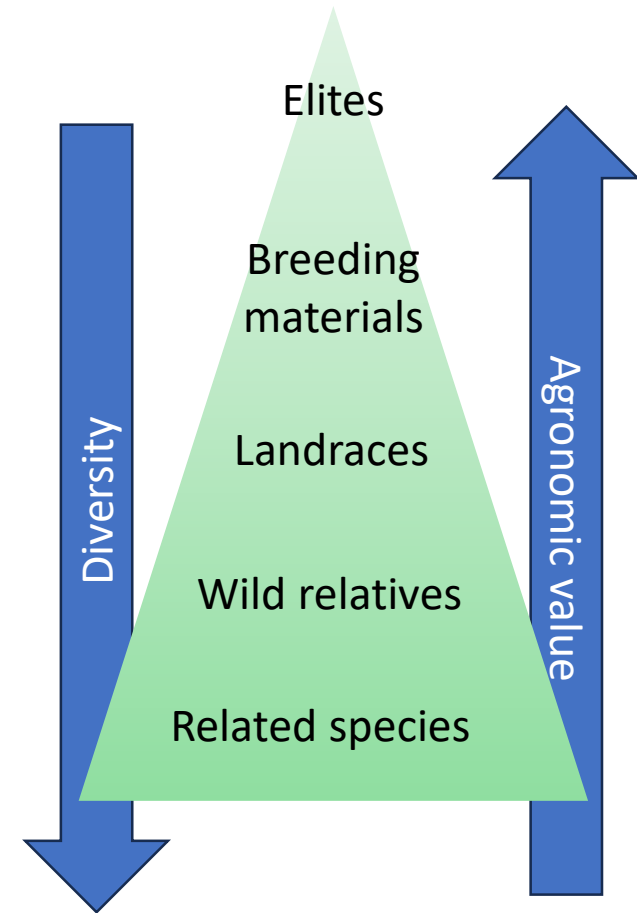

To map genotype-trait associations means to **detect** , **locate**, and **assess the importance** of «genetic factors» affecting traits

Mapping genotype-trait associations in plant genetic resources unlocks key information for **breeding**:

1. Identify new genetic factors/alleles that can be used to improve traits of agronomic performance and adaptation
2. Predict the genomic potential for any given individual with regards to a trait of interest
3. Understand the genetic basis of traits of interest

The value of diversity contributed by plant genetic resources

- Depending on the type of allele pool, there are different types and amounts of diversity available (and hence a different potential in association studies)

Agronomy

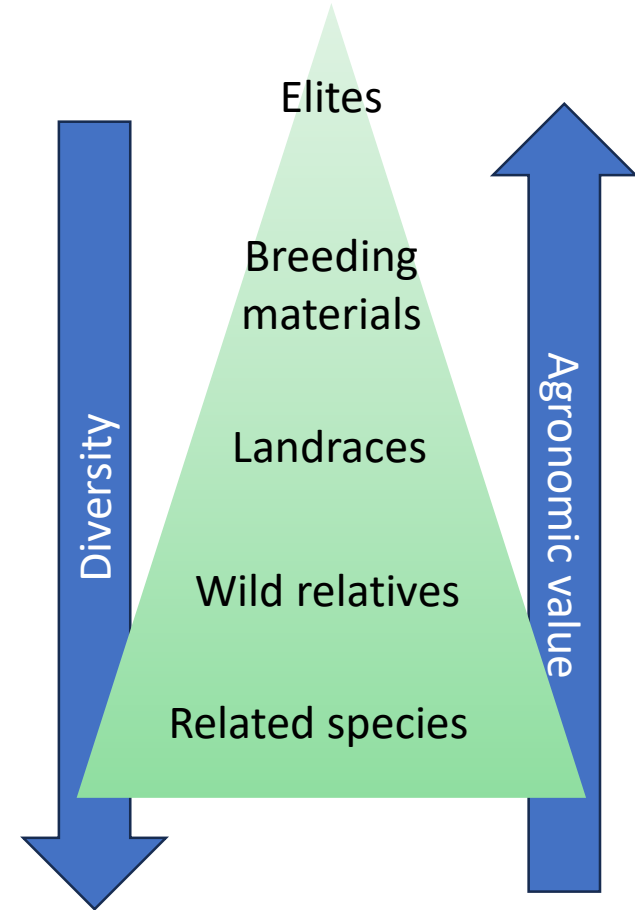

- Yield and yield component traits (e.g. spike size)
- Developmental traits (e.g. flowering time)
- Quality traits (e.g. micronutrients)
- Market traits (e.g. colour, taste)

Adaptation

- Resistance to abiotic stress (e.g. drought)
- Resistance to biotic stress (e.g. disease)

Future-proofing

- What is needed for adaptation to future climates (e.g. frequency and intensity of extreme events)

Our working hypothesis: there are one or more «genetic factors» somewhere on the genome affecting a trait of interest

Gene X

We already know it's not an easy job:

- Most interesting traits are controlled by multiple genetic factors
- Most plant genomes are complex; loci may interact
- It is not really like finding a needle in a haystack; it is **finding a needle in pile of needles**

Reverse genetics

Gene(s)

What trait arises from
the perturbation of a
DNA sequence?

Trait(s)

Forward genetics

Trait(s)

Is variation of a trait
associated with
genotypic variation?

Gene(s)

Reverse genetics in plant genetic resources

- Mutagenic agents (chemical/physical) are used to create new variation
- If you observe an interesting trait in an individual, and if the mutation is known, it is possible to link it to the trait to the genomic location
- Mutations can either be *untargeted* or *targeted* (more to come once we discuss genome editing)

Forward genetics in plant genetic resources

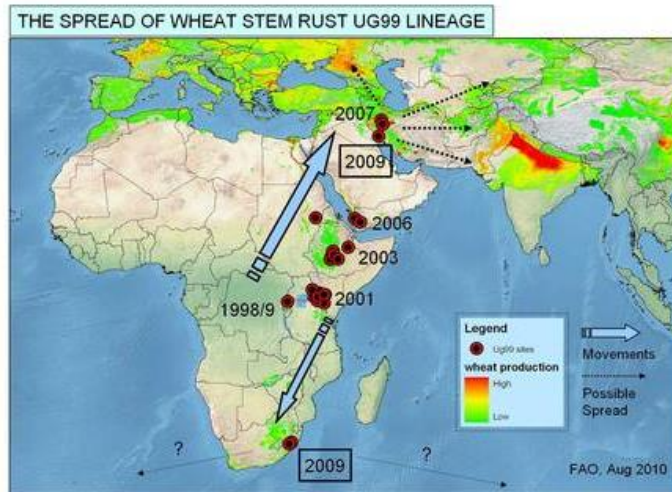

- Stem rust (*Puccinia graminis* f. sp. *tritici*) is a devastating disease in wheat that may cause up to 100% losses
- A major target of breeding from the green revolution
- There is plenty of resistance genes that have been introgressed from wild species
 - *T. timopheevi*
 - *Ae. ventricosa*
 - *Ae. speltoides*
 - *Ae. tauschii*
 - *S. cereale*
 - *T. monococcum*
 -

- Race Ug99 (TTKSK) emerged and overcame resistance of many known genes
- New resistance alleles were found in african landrace materials and transferred to elite materials to confer resistance

RESEARCH ARTICLE

Metabolic Engineering to Enhance Provitamin D₃ Accumulation in Edible Tomatoes

Sunmee Choi,^{1,†} Min Kyoung You,^{1,†} Yun-A Jeon,^{1,†} Jaebok Lee,¹ Jinhwa Kim,¹ Young Jin Park,² Jeongmo Kim,¹ Jongjin Park,¹ Jae Kwang Kim,² and Sunghwa Choe^{1,3,*}

Abstract

Ensuring adequate levels of vitamin D₃ in the human diet has long been an important objective in crop breeding, as most crops have extremely low levels of this compound. To address this challenge, we have employed the CRISPR-Cas9 gene editing system in tomatoes to induce loss-of-function mutations in one of the two *DWARF5* genes, a homologue of the human dehydrocholesterol Δ^7 -reductase gene. Lines with knocked out *SIDWF5A* gene exhibited visually indistinguishable phenotypes, yet remarkably accumulated provitamin D₃ levels as high as 6 $\mu\text{g/g}$ dry weight (DW) in the red fruits. As the daily recommended intake of vitamin D is 20 μg (800 IU), consuming a single ripe fresh tomato weighing 150 g (equivalent to 15 g DW) has the potential to significantly alleviate widespread vitamin D deficiencies worldwide.

A recipe for forward genetics: genome-wide association studies (GWAS)

Our ingredients:

1. **Genetic materials**, a set of plant genetic resources in which variation is present for certain traits
2. **Phenotypic values** measured on the set of genetic materials and representing variation of interest
3. **Molecular markers** typed on the set of genetic materials; most commonly SNPs, which are bi-allelic and distributed genome wide
4. **Appropriate statistics** to connect genotypes and phenotypes; many methods, same underlying reasoning

- Many different methods, same underlying reasoning: is there any given allele (marker) associated with the value of the trait of interest?
- In other words, we want to know whether our response variable (y , the phenotype) is associated with our explanatory variable (x , the marker)
- We can address this in a simple statistical framework based on a linear model

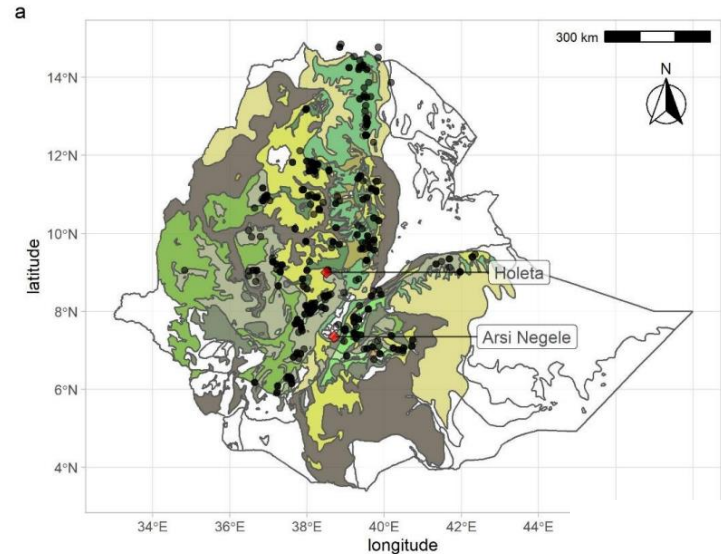

$$y = \beta_0 + \beta_1 x + \varepsilon$$

$$H_0: \beta_1 = 0 \quad H_A: \beta_1 \neq 0$$

The recipe at work

Research question: climate change is affecting seasonal rainfall distribution in Ethiopia; there is the need to steer breeding towards early flowering genotypes to improve local adaptation; plant genetic resources may have useful alleles to contribute to this

1. Genetic materials: A representative collection of 250 Ethiopian barley landraces and breeding lines

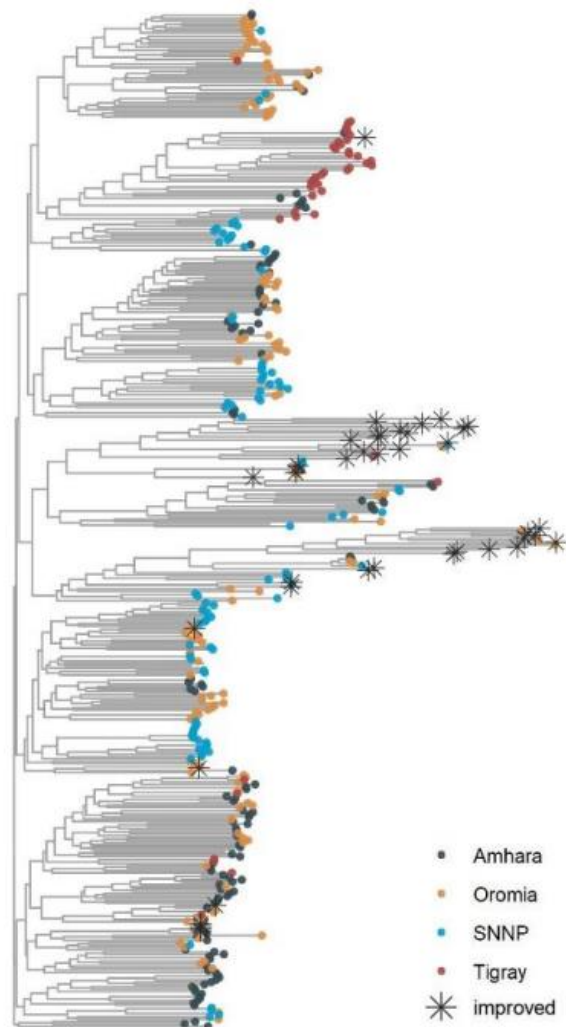

2. **Phenotypic values:** Days to flowering measured on all genetic materials for which genotypic data is also available

3. Molecular markers: 23K+ SNPs describing the diversity of genetic materials across the whole genome

4. Appropriate statistics

4. Appropriate statistics

- Each individual is different from the others; when we genotype them with SNPs, we obtain biallelic markers at each locus, with different outputs depending on their allelic diversity
- We don't really need to worry about nucleotides; let's rather think in terms of alleles, and let's call the allele **0** when it is the same as the reference genome and **1** when it is different

Homozygous reference: 00

Heterozygous: 01

Homozygous alternative: 11

Running a GWAS fitting a linear model to connect phenotypes and alleles at each locus

	ID1	ID2	ID3	ID4	ID5	ID6	ID7	...	ID N
									
SNP 1									
SNP 2									
SNP N									
SNP 1	00	00	01	01	11	00	11		00
SNP 2	01	11	00	01	00	11	11		11
SNP N	11	00	00	11	11	11	00		01

No association; this is the outcome expected on most tests (as most of the markers/loci have nothing to do with the trait)

$$y = \beta_0 + \cancel{\beta_1 x} + \varepsilon$$

Association; it seems that the response variable is associated with the explanatory variable, and we expect it to happen rarely. To what extent the association is significant, the statistics tells us

$$y = \beta_0 + \beta_1 x + \varepsilon$$

- The model is tested on all markers; if you have 1M markers, that's 1M tests!
- Each test is specific to a marker, which is specific to a genomic location
- The common representation of the outcome is a **Manhattan plot** which puts together position on the genome (x) and significance of the associated test (y)

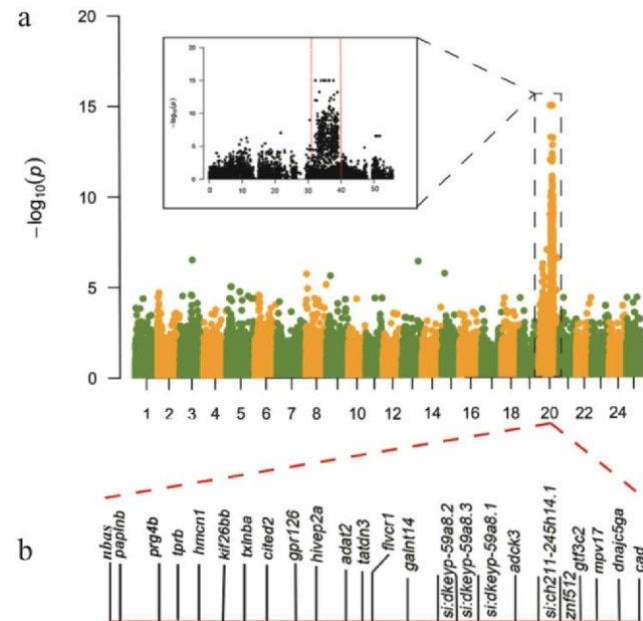

Remember that SNP markers, however many they may be, seldom represent the full extent of variation in the genome

- Markers are our **proxy** to represent variation in the DNA level; they are the mean to an end and not the end itself

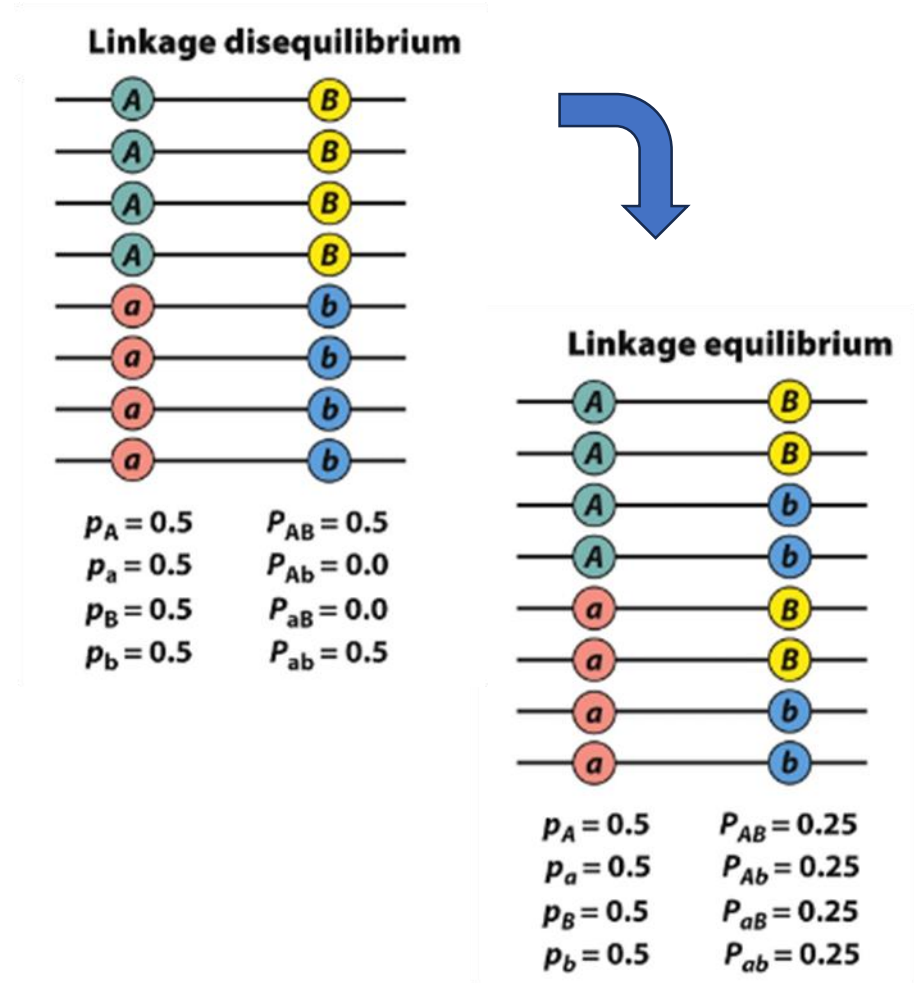

The reason why we capture the «effect» of a specific genetic factor on the value of the trait through GWAS is that **linkage disequilibrium (LD)** exists between the marker and the causative variant

A key concept when it comes to mapping is that of linkage disequilibrium (LD)

- LD is the non random association of alleles at different loci in a given population
- It occurs when alleles at different loci are inherited together more often than expected by chance
- Recombination decreases LD
- Throughout time, populations move from disequilibrium to equilibrium (assuming that recombination occurs)

Back to Ethiopian barley genetic resources now

What's next?

- Characterize gene models in the region
- Develop segregating populations to fine map genetic elements
- Design cheap markers tagging loci of interest
- Derive sequences to be tested with **reverse genetics**

Trait determination complexity

- Most traits of agronomic interest are complex
- They have a quantitative manifestation that is the result of the cumulative contribution and interaction of n loci, each with a fraction effect on the trait
- Hence, the term Quantitative Trait Loci (QTL) mapping

Caveats

The identification of genotype-trait association is a challenging effort depending on many variables, including:

- Diversity available in plant genetic resources
- Sample size and experimental design (statistical power)
- Nature and extent of molecular characterization of the mapping panel / Frequency of recombination (linkage disequilibrium)
- Organization of the genetic diversity in the population (genetic structure)
- Complexity of the trait and heritability

Development of mapping populations

Nested Association Mapping (NAM) panel

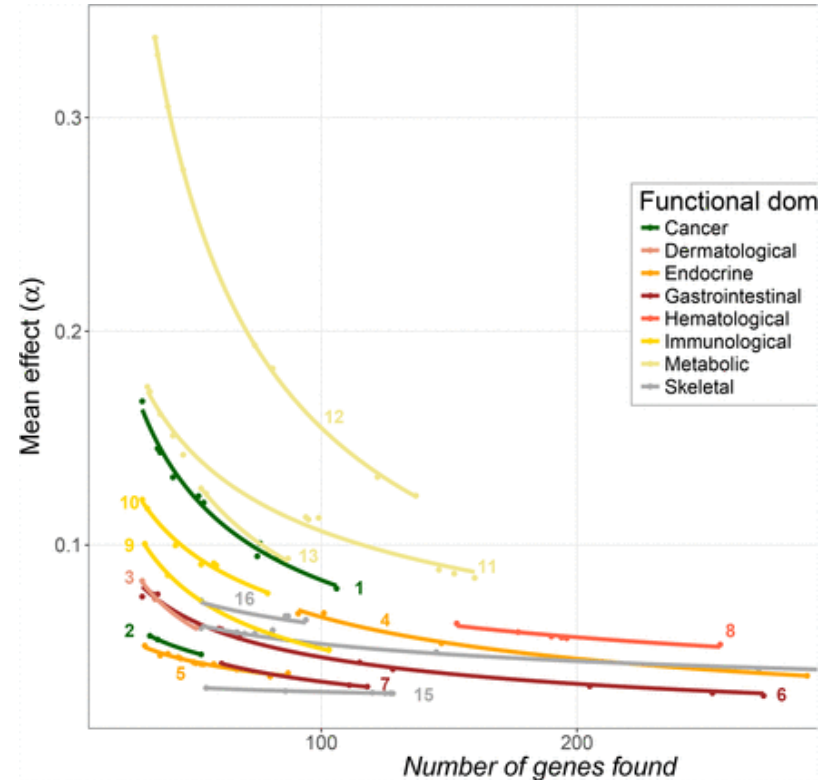

Multi-parent Advanced Generation Inter-Cross (MAGIC)

An issue with complexity

- It is becoming increasingly clear that traits are controlled by manifold, small effect loci
- Quantitative genetic mapping studies are typically underpowered to capture small effects (few cases, many variables)
- Large human studies (e.g. UK BioBank) are filling in the gap

Heritability is the proportion of phenotypic variance that can be explained by genotypic variance; the higher, the easier to map

GWAS/forward genetics is a statistical exercise. Presence of a QTL/marker-trait association is defined on the basis of a significance threshold, and depending on it there's a certain chance of committing Type I and Type II errors

Type I and Type II Error

Null hypothesis is ...	True	False
Rejected	Type I error False positive Probability = α	Correct decision True positive Probability = $1 - \beta$
Not rejected	Correct decision True negative Probability = $1 - \alpha$	Type II error False negative Probability = β

Probability of making Type I and Type II errors

Reverse genetic approaches may be used to «validate» associations

Once marker-trait associations are identified

Design markers that can be used by breeders to follow the segregation of a trait of interest

1. Assay components:

A) KASP Assay Mix: consists of 2 allele specific primers and 1 reverse primer.

B) KASP Master Mix: contains universal fluorescent probes, Taq polymerase and dNTP's in an optimised buffer solution.

C) Sample DNA: DNA contains the SNP of interest.

A) KASP Assay Mix

Allele-specific forward primers:

B) KASP Master Mix

C) DNA template (sample)

2. Denatured template and annealing components – PCR round 1:

In the first round of PCR, one of the allele-specific primers matches the target SNP and with the common reverse primer, amplifies the target region.

3. Complement of allele-specific tail sequence generated – PCR round 2:

4. Signal generation – PCR round 3:

In further rounds of PCR, levels of allele-specific tail increase. The fluor labelled part of the FRET cassette is complementary to new tail sequences and binds, releasing the fluor from the quencher to generate a fluorescent signal.

Legend

- Allele-1 tail FAM-labelled oligo sequence
- Allele-2 tail HEX-labelled oligo sequence
- Common reverse primer
- F FAM dye
- H HEX dye
- Target SNP
- Q Quencher

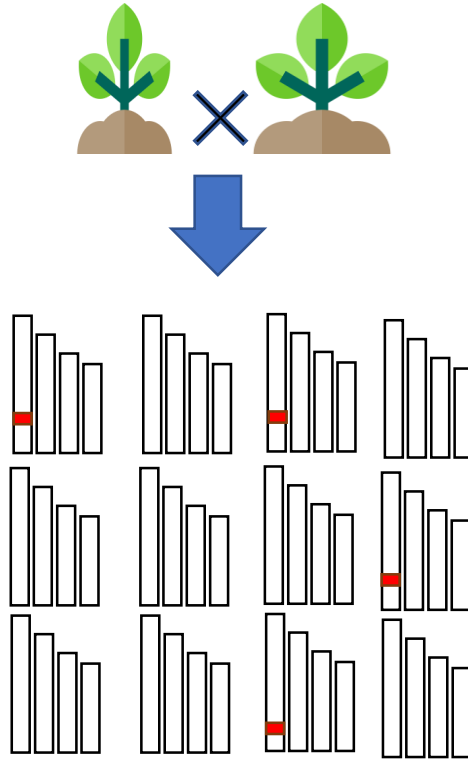

(Reverse primer binds, elongates and makes a complementary copy of the allele-1 tail.)

Use of mapping information for breeding

Selection based on traits

Selection based on markers

Once a marker-trait association is discovered, it can be used to accelerate the development of new varieties with improved traits

Modifying genes

Forward genetics in plant genetic resources

- Stem rust (*Puccinia graminis* f. sp. *tritici*) is a devastating disease in wheat that may cause up to 100% losses
- A major target of breeding from the green revolution
- There is plenty of resistance genes that have been introgressed from wild species
 - *T. timopheevi*
 - *Ae. ventricosa*
 - *Ae. speltoides*
 - *Ae. tauschii*
 - *S. cereale*
 - *T. monococcum*
 -

- Race Ug99 (TTKSK) emerged and overcame resistance of many known genes
- New resistance alleles were found in african landrace materials and transferred to elite materials to confer resistance

- It is becoming increasingly clear that traits are controlled by manifold, small effect loci
- Forward genetics are typically underpowered to capture small effects (few cases, many variables)
- Large studies are starting to fill in the gap

It is easier to map QTL for disease resistance than to map QTL for yield

The case of the missing heritability

When scientists opened up the human genome, they expected to find the genetic components of common traits and diseases. But they were nowhere to be seen. **Brendan Maher** shines a light on six places where the missing loot could be stashed away.

From López-Cortegano, Caballero 2018

Towards gene identification

The mapping resolution depends on recombination density

It is very infrequent to be able to identify individual causative variants, and this depends on a number of factors:

- Marker density
- Recombination density
- Complexity of the trait
- Quality of the annotation

Development of mapping populations

Nested Association Mapping (NAM) panel

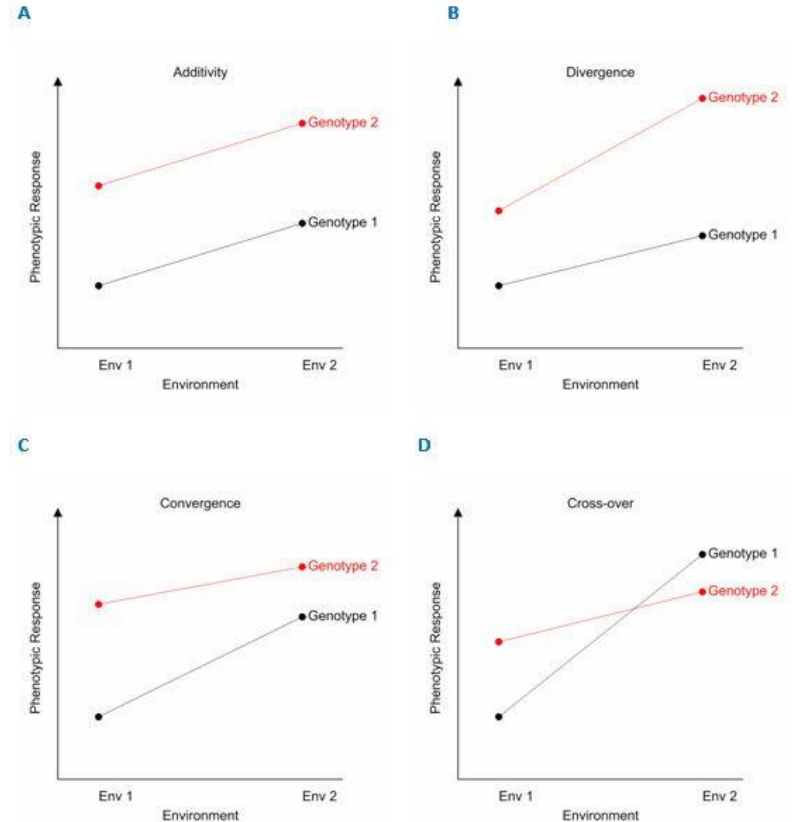

Multi-parent Advanced Generation Inter-Cross (MAGIC)

Decomposing phenotypic variance in quantitative traits

$$V_p = V_g + V_e + V_{ge}$$

- The performance of each individual is determined both by its genotype composition and by the environment
- The best performer in one environment may not be the best in another

Decomposing genotypic variance in quantitative traits

$$V_G = V_A + V_D + V_I$$

Genetic variance can also be decomposed in fundamental components:

- Additive genetic variance (A), refers to the deviation from the mean phenotype due to inheritance of a particular allele and this allele's relative effect on phenotype, i.e., relative to the mean phenotype of the population
- Dominance variance (D) due to interactions between alternative alleles at a specific locus
- Interaction or epistatic variance (I) due to interaction between alleles at different loci

The heritability of a given trait is calculated as the fraction of the trait variance that can be explained by genotypic variance

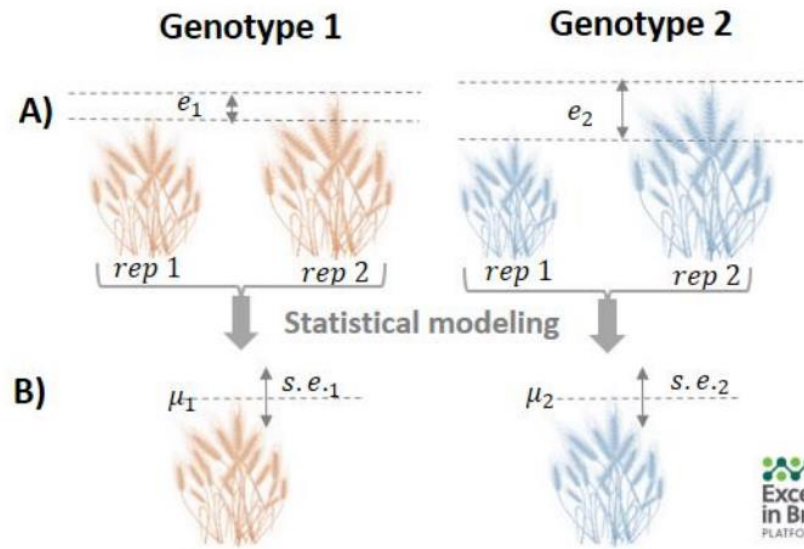

$$H^2 = \frac{\sigma_g}{\sigma_g + \sigma_e}$$

Broad sense heritability: all sources of genetic variance are considered

$$h^2 = \frac{\sigma_g}{\sigma_g + \sigma_e}$$

Narrow sense heritability: only additive genetic variance is considered

- If H^2 is 0, none of the phenotypic variation can be explained by the genetic variation, it is all due to variation in the environment
- If H^2 is small, the trait is strongly influenced by the environment (e.g., yield)
- If H^2 is large, the trait is only slightly influenced by the environment (e.g. flower colour).

Heritability:

Based on error plot variance

$$H_{Standard}^2 = \frac{\sigma_g^2}{\sigma_g^2 + (\sigma_e^2/n)}$$

Based on average genotype standard error

$$H_{Piepho}^2 = \frac{\sigma_g^2}{\sigma_g^2 + \bar{v}_{\Delta}^{BLUE}}$$

Characters

Heritability

Broad sense (%)

Narrow sense (%)

Characters	Broad sense (%)	Narrow sense (%)
Plant height (cm)	71	48
Number of panicles / plant	30	14
Number of spikelets / panicle	32	29
Number of fertile spikelets / panicle	36	27
Percentage spikelets fertility / plant	49	47
100 grain weight / plant (g)	67	50
Grain yield / plant (g)	32	19

In a breeding perspective,
heritability is quite
important

Common misconceptions about heritability

- **“A heritability of .4 means that 40% of the trait is determined by genetics”.** Nope. A heritability of 0.4 indicates that 40% of all the phenotypic variation for that trait is due to variation in genotypes for that trait (and not that in each plant 0.4 of the phenotype is determined by genes)
- **“A low heritability means that trait is not determined by genes”.** Also wrong; low heritability may be due to low variance (in the population) or too much error
- **“A heritability is a fixed value”.** It really is a population value and depends on genetic materials and experimental conditions in which variances are assessed
- **“A high heritability implies a major-effect QTL”.** It could actually be due to a number of different QTL (each with small effects)

QTL mapping

- A QTL is a locus contributing to the phenotypic value of a complex (multigenic) trait
- QTL mapping aims at the dissection of complex traits into Mendelian factors: understand their location and their relative importance

QTL mapping to-dos

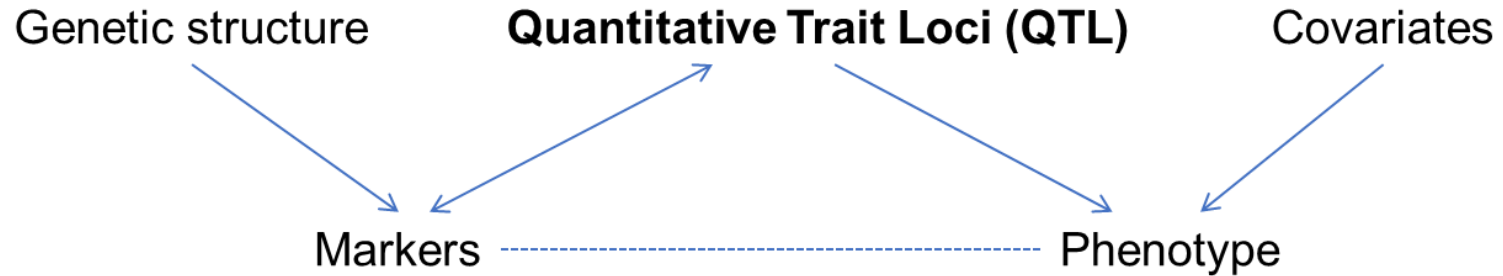

- Control environment & vary genetics
- Use a panel of genetically diverse plants with different trait levels
- Leverage statistical association between alleles and trait levels to find genomic loci and possibly genes

$$y = \beta_0 + \beta_1 x + \varepsilon$$

The identification of QTL is a challenging effort depending on many variables, including:

- Diversity in the mapping panel
- Frequency of recombination (linkage disequilibrium)
- Nature and extent of molecular characterization of the mapping panel
- Complexity of the trait (heritability)
- Sample size (statistical power)

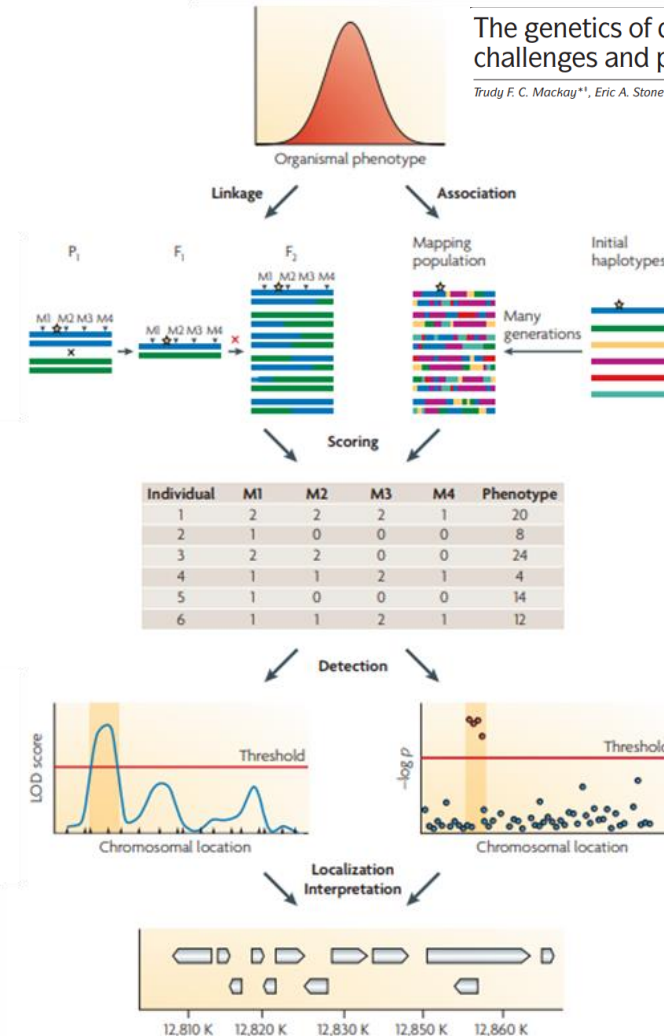

QTL mapping requires four things:

1. Segregating genetic materials
2. Genetic markers characterizing the mapping population
3. Consistent and reproducible phenotypic data
4. Appropriate statistics

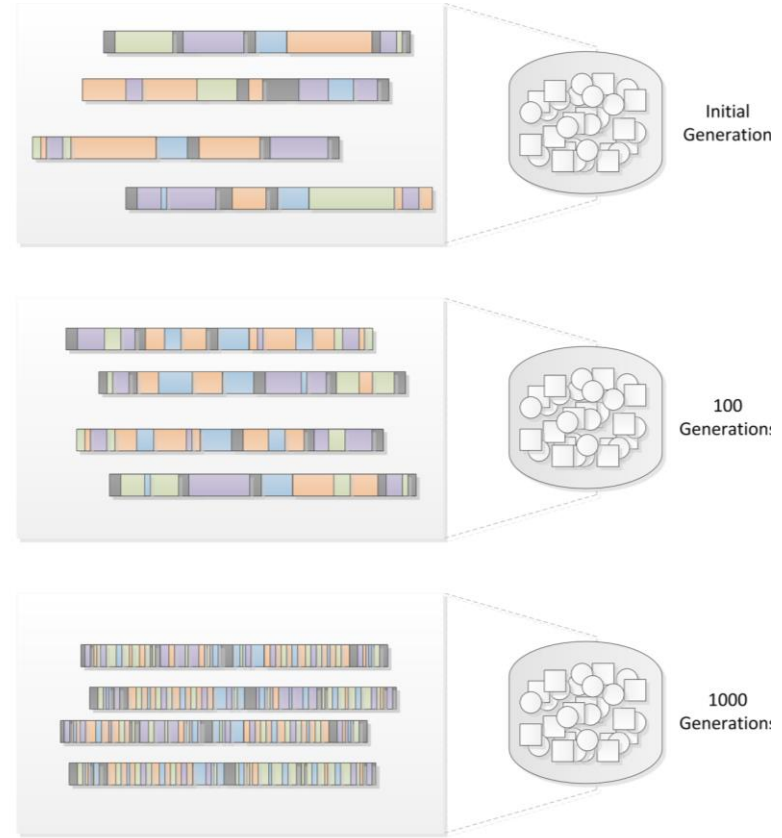

The genetics of quantitative traits: challenges and prospects

Trudy F. C. Mackay¹, Eric A. Stone^{1b} and Julien F. Ayroles^{1*}

Diversity panels → groups of individuals collected from nature and resulting from an history of intermating

- Typically high diversity
- High recombination density
- Differently from experimental crosses, the pedigree (derivation) of individuals is unknown

Multiparental mapping populations (MPPs) → artificial segregant populations developed intercrossing 2+ parental lines

- Typically high diversity
- High recombination density
- Known pedigree and balanced diversity

Nested Association Mapping (NAM) panel

Multi-parent Advanced Generation Inter-Cross (MAGIC)

2. Molecular markers

- Genotyping information is necessary to characterize the genetic diversity in the mapping population
- You have all sort of molecular markers to choose from, the most accurate being single nucleotide polymorphisms (SNPs)

Individual sequences

Haplotypes

A G T

B T A

A G A

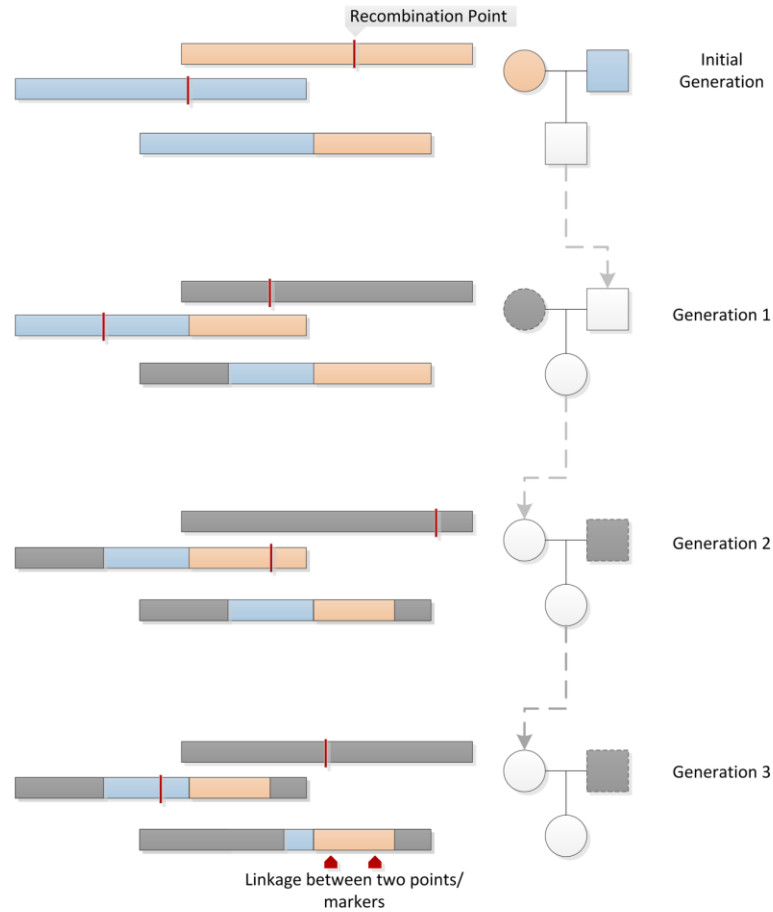

- A haplotype is a combination of alleles at multiple loci that are transmitted together on the same chromosome
- Looking back at genetic materials, a haplotype represents a group of loci within an organism that was inherited together from a single parent.

A key concept when it comes to mapping is that of linkage disequilibrium (LD)

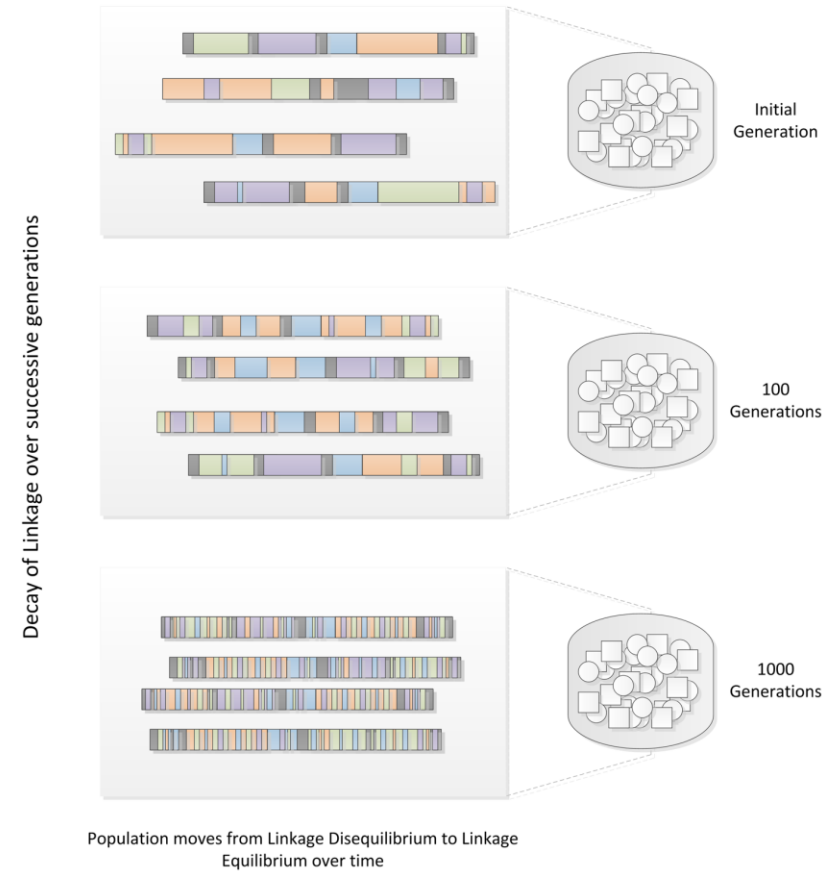

- LD is the non random association of alleles at different loci in a given population
- It occurs when alleles at different loci are inherited together more often than expected by chance
- Recombination decreases LD
- Throughout time, populations move from disequilibrium to equilibrium (assuming that recombination occurs)

Linkage Within A Family

Linkage Disequilibrium Within A Population

3. Well measured phenotypes

- In order to support QTL mapping, measurements must be repeatable (remember $G \times E$) and accurate (lower error)
- Nowadays, phenotyping comes in a –omics dimension

4. Appropriate statistics

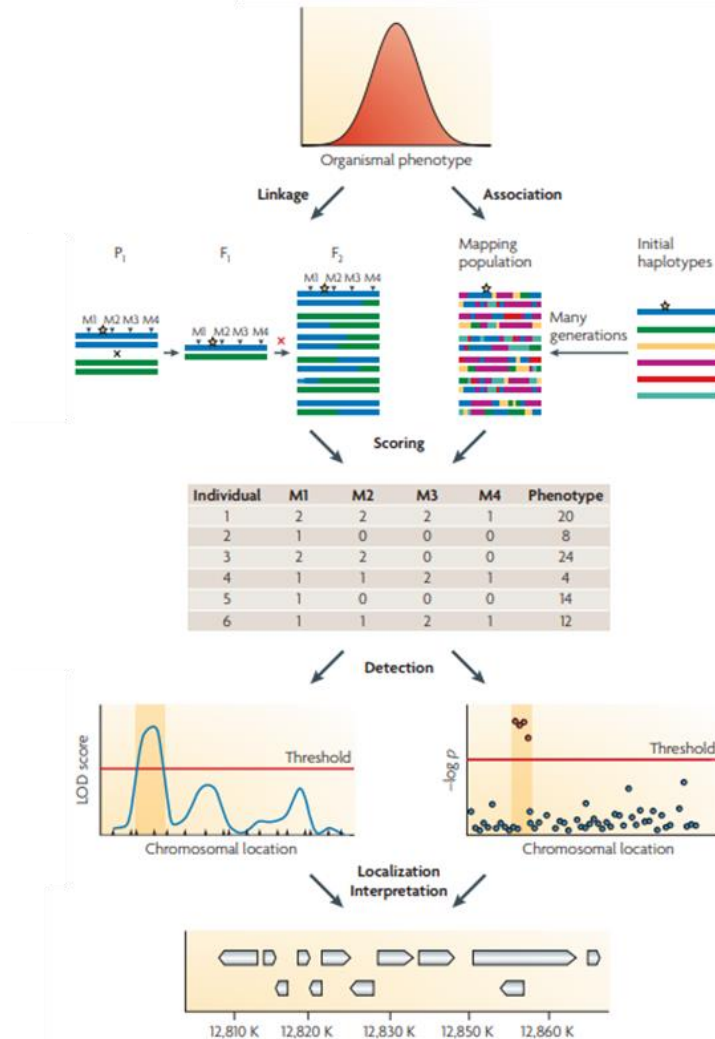

- Many different methods exist, depending on population, distribution of traits, genetic mechanisms considered, molecular markers, ...

$$y = \beta_0 + \beta_1 x + \varepsilon$$

- Two main avenues:
 - **Linkage / interval mapping;** When pedigree is known (artificial populations) and intervals of markers – rather than individual markers – is used to support mapping. The resulting statistic is the logarithm of odds (LOD), or the log of the probability of having a QTL in a specific location over the probability of not having it
 - **Genome-wide association studies / LD mapping;** a mapping conducted marker by marker, used in diversity panels. The resulting statistic is a p-value coming from testing the alternative hypothesis of a genotypic effect on the trait

Linkage mapping

- Low marker density required
- Fully known pedigree
- More robust
- Limited variation
- Low definition
- Time demanding

Association (GWAS)

- High marker density necessary
- Hidden structure, LD
- Higher false positive rate
- Broad variation
- High definition
- Faster, cheaper

Five generations of self pollinating

Individual Lines in the Subject Population

Forward genetics is a statistical exercise (LOD or pvalue). Presence of a QTL is defined on the basis of a significance threshold

$$y = \beta_0 + \beta_1 x + \varepsilon$$

$$H_0: \beta_1 = 0 \quad H_A: \beta_1 \neq 0$$

Type I and Type II Error

Null hypothesis is ...	True	False
Rejected	Type I error False positive Probability = α	Correct decision True positive Probability = $1 - \beta$
Not rejected	Correct decision True negative Probability = $1 - \alpha$	Type II error False negative Probability = β

Probability of making Type I and Type II errors

Multiple testing problem: when conducting multiple statistical tests simultaneously, the chance of incorrectly rejecting a true null hypothesis (false positive) increases

- **Bonferroni:** the nominal test p-value (typically 0.05) is divided by the number of independent tests performed
- **False Discovery Rate (FDR):** an adjusted p-value distribution that is specific to each test and that takes in account the expected proportion of false positives among all significant tests
- **Permutations:** scrambling the phenotypic values and looking for QTL (expecting not to find any). Repeat a large n of times and produce a distribution of statics that represents noise. Then pick a threshold according to the distribution

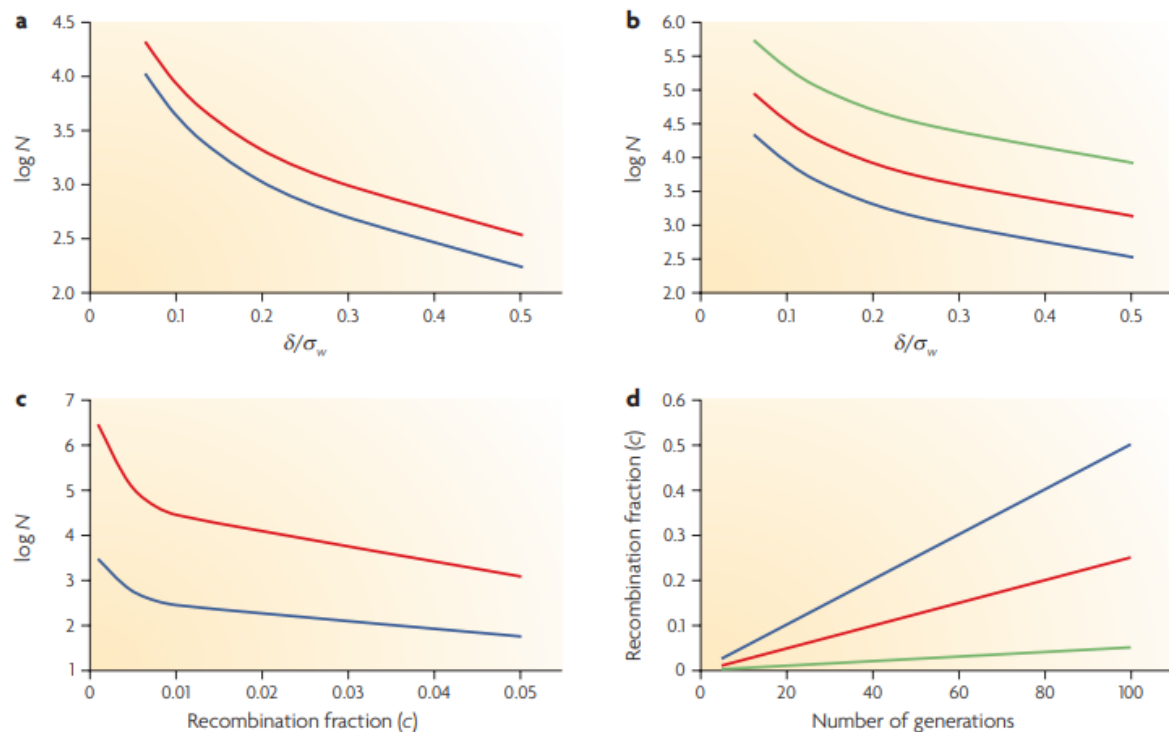

Figure 1 | Power to localize and detect quantitative trait loci. **a** | Numbers of individuals (\log_{10} scale) required to detect quantitative trait loci (QTLs) for a range of effect sizes (δ/σ_w) in backcrossed (blue) and F_2 (red) linkage mapping populations. **b** | Numbers of individuals (\log_{10} scale) required to detect QTLs for a range of effect sizes in association mapping populations in which the minor allele frequency is 0.5 (blue), 0.25 (red) and 0.1 (green). **c** | \log_{10} of the number of individuals required to detect at least one recombinant in an interval of size c ($c = 100$ centiMorgans; cM) (blue) and \log_{10} of the number of marker genotypes needed to localize QTLs per 100 cM (red). **d** | The expected frequency of recombinants after t generations of recombination in a random mating population, for a per generation recombination fraction of $c = 0.01$ (blue), $c = 0.005$ (red) and $c = 0.001$ (green). δ , average difference in the trait phenotype between marker allele genotypes; σ_w , phenotypic standard deviation of the trait within marker genotype classes.

The combined resample model inclusion probability (RMIP) details the number of models one or more markers located within 3 cM of the stated association was selected out of the 100 models constructed for each trait (PHT, EHT, DTA, NPH). Each of the 100 models was calibrated from a family-stratified sampling of RILs during bootstrapped joint-linkage mapping. Mb denotes megabase positions in maize RefGenV1. cM denotes centimorgan positions of the composite NAM family genetic map.

From QTL to genes

- Typically QTL regions identified contain many genes/genetic factors
- Molecular markers are a proxy of genetic factors to which they are associated through linkage disequilibrium (LD)

Mapping QTLs in breeding for drought tolerance in maize (*Zea mays* L.)

Hesham A. S. Agrama^{1,*} & Mounir E. Moussa²

¹Maize Research Department, Agricultural Research Centre, Field Crops Research Institute, Egypt; ²Department of Genetics, Faculty of Agriculture, Alexandria University, Egypt; (* author for correspondence)

Received 11 August 1995; accepted 15 March 1996

Grain yield in the maize (*Zea mays* L.) plant is sensitive to drought in the period three weeks either side of flowering. Maize is well-adapted to the use of restriction fragment length polymorphisms (RFLPs) to identify a tight linkage between gene(s) controlling the quantitative trait and a molecular marker. We have determined the chromosomal locations of quantitative trait loci (QTLs) affecting grain yield under drought, anthesis-silking interval, and number of ears per plant. The F₃ families derived from the cross SD34(tolerant) x SD35(intolerant) were evaluated for these traits in a two replicated experiment. RFLP analysis of the maize genome included non-radioactive DNA-DNA hybridization detection using chemiluminescence. To identify QTLs underlying tolerance to drought, the mean phenotypic performances of F₃ families were compared based on genotypic classification at each of 70 RFLP marker loci. The genetic linkage map assembled from these markers was in good agreement with previously published maps. The phenotypic correlations between yield and other traits were highly significant. In the combined analyses, genomic regions significantly affecting tolerance to drought were found on chromosomes 1,3,5,6, and 8. For yield, a total of 50% of the phenotypic variance could be explained by five putative QTLs. Different types of gene action were found for the putative QTLs for the three traits.

Figure 2. Genetic linkage map was generated using an F₃ population derived from SD34 x SD35. The map included 70 RFLP loci, scored in about 120 individuals, and linkage analysis was done using MAPMAKER v2.0.

Figure 3. QTL likelihood maps indicating LOD score for grain yield under drought (GYD), anthesis-silking interval (ASI), and ears per plant (EAR). The horizontal line at a height of 2.2 indicates the stringent threshold that the LOD score must cross to allow the presence of a QTL to be inferred.

Using high-throughput multi-phenotyping to decipher the architecture of maize drought

Abstract

Background: Drought threatens the food supply the dynamic responses of plants to drought to drought tolerant crops, as the genetic controls of these responses.

Results: Here we develop a high-throughput multi-phenotyping pipeline to noninvasively phenotype 368 maize genotypes over a course of 98 days, and collected multiple phenotypic traits using camera scanning, hyperspectral imaging, and X-ray. We develop high-throughput analysis pipelines to extract traits from these data. Of these i-traits, 10,080 were effective and heritable. We use genetic mutation analysis to validate two candidate genes as drought-tolerant genetic markers. We use genetic mutation analysis to validate two candidate genes as drought-tolerant genetic markers. We use genetic mutation analysis to validate two candidate genes as drought-tolerant genetic markers.

Conclusion: Our study demonstrates that combining optical phenotyping and GWAS is a novel and effective approach to decipher the genetic architecture of complex traits and clone

and inspection
